## **EXECUTIVE SUMMARY**

Manufacturers of biotechnological/biological products frequently make changes to manufacturing processes of their products both during development and post-approval.

Demonstration of comparability of the pre- and post change product is a sequential process, beginning with quality studies (limited or comprehensive) and supported, as necessary, by non-clinical, clinical and/or pharmacovigilance studies.

This guideline gives advice on the non-clinical and clinical requirements of the comparability exercise comparing post-change product to pre-change product where manufacturing process changes are made by a single manufacturer, including those made by a contract manufacture. This guideline will address the requirements for non-clinical and/or clinical bridging studies to demonstrate that the manufacturing change has no impact on safety and efficacy.

The selection of non-clinical and clinical studies is product-driven, i.e. a strategy for comparability testing should be chosen that best predicts or detects clinically relevant differences with sufficient accuracy.

This guideline replaces the guideline on comparability of medicinal products containing Biotechnology-derived proteins as active substance (CPMP/3097/02).

### **1. INTRODUCTION**

Manufacturers of biotechnological/biological products frequently introduce changes in the manufacturing process of a given product (both before and after the granting of a marketing authorisation). It is assumed that the product's physico-chemical properties and *in vitro* / *in vivo* biological activity are well characterised according to state of the art methods.

For most changes to the manufacturing process, physico-chemical and (quality related) biological testing can demonstrate that there is no difference in quality of the product that could adversely impact the safety and efficacy of a product. Thus the comparability exercise may be limited to strict process validation of the change or be extended to various quality criteria such as in-process controls, thorough analytical and biological characterisation of the product and stability data. However, sometimes an effect on efficacy and/or safety can be expected on the basis of observed difference(s) or cannot be ruled out in spite of the state of the art physico-chemical and biological tests. In such cases, additional non-clinical and/or clinical studies will be necessary.

The type and extent of such studies are variable and will be dependent on numerous factors related to the drug substance and the drug product, such as

- knowledge of the molecule and of other molecules of the same class
- the stage of development of products not yet authorised
- the findings in the physico-chemical and biological comparability exercise
- the intended clinical use.

### **2. SCOPE**

The principles adopted and explained in this document apply to proteins and polypeptides, their derivatives, and products of which they are components, e.g., conjugates. These proteins and polypeptides are produced by recombinant or non-recombinant cell-culture expression systems and can be highly purified and characterised using an appropriate set of analytical procedures, in cases when

- Manufacturing process changes are made by a single manufacturer, including those made by a contract manufacturer, who can directly compare the processes, analytical in-process data and results from the analysis of pre-change and post-change product; and
- Manufacturing process changes are made in development or for which a marketing authorisation has been granted.

The principles outlined in this document might also apply to other product types such as proteins and polypeptides isolated from tissues and body fluids. In this case, manufacturers are advised to consult relevant guidelines and the competent Regulatory Authority to determine applicability.

### **3. LEGAL BASIS**

This guideline has to be read in conjunction with the introduction and general principles (4) and part II of the Annex I to Directive 2001/83/EC as amended.

### **4. MAIN GUIDELINE TEXT**

#### **4.1 Need for non-clinical and clinical studies – a risk-based approach**

Demonstration of comparability is a sequential process, beginning with quality studies (limited or comprehensive) and supported, as necessary, by non-clinical, clinical and/or pharmacovigilance studies. If a manufacturer can provide evidence of comparability through physico-chemical and biological studies, then non-clinical or clinical studies with the post-change product are not warranted. In other cases, additional non-clinical and/or clinical data will be required.

The need, extent and nature of non-clinical and clinical comparability studies will be determined on a case-by-case basis in consideration of various factors that may be associated with risk, such as:

- The process complexity, the nature of the change, the potential impact on the molecule structure and on the final product profile.
- The nature, and extent of differences demonstrated by the physico-chemical and quality-related biological characterisation, including product-related substances, impurity profile, stability and excipients. Thus, well-characterised differences may provide a background for a rational and focused approach with respect to the need for non-clinical and clinical studies.
- Product complexity, including heterogeneity and higher order structure and the availability, capabilities and limitations of analytical tests. If the analytical procedures used are not sufficient to discern relevant differences that can impact the safety and efficacy of the product, additional non-clinical and/or confirmatory clinical testing may be necessary.
- Structure-activity relationship and strength of the association of quality attributes with safety and efficacy;
- Relationship between the therapeutic protein and endogenous proteins and the severity of (potential) consequences for immunogenicity; e.g. risk of autoimmunity
- Mode(s) of action: unknown or multiple modes of action complicate the evaluation of the impact of changes
- Therapeutic indications/target patient groups - The impact of possible differences can vary between the target populations covered by the different indications.
- Posology, e.g., dosing regimen and route of administration, for instance, repeated administration via the subcutaneous route is more likely to be associated with immunogenicity than intravenous administration of a single dose
- The therapeutic window/dose-response curve
- Previous experience, e.g., immunogenicity, safety. Experience with the pre-change product or with other products in the same class can be relevant. However, biotechnology-derived proteins should be considered individually.

For products in development, all these points above should be taken into consideration. However, the extent of the comparability studies will likely increase if manufacturing changes are introduced at the later stages of clinical development. A change after conduct of confirmatory efficacy and safety studies represents the most challenging situation.

The selection of non-clinical and clinical studies is product-driven, i.e. a strategy for comparability testing should be chosen that best predicts and detects clinically relevant differences with sufficient accuracy.

#### 4.2 Non-clinical data

If evidence from physico-chemical studies and quality-related biological studies alone is not sufficient to establish comparability of the pre- and post-change products, either because these data reveal a difference in the two products, or because the nature of the manufacturing change is such that a difference cannot be excluded based on the available quality data alone, then data from non-clinical studies may provide useful signals of potential therapeutic and safety differences.

In some cases it may be appropriate to undertake few or even no non-clinical studies, but in other situations a more detailed evaluation may be helpful. It is important to note that the design of an appropriate non-clinical study program requires a clear understanding of the structure and activity of the product. Relevant guidance documents, notably the “Note for guidance on non-clinical safety evaluation of biotechnology derived pharmaceuticals” (CPMP/ICH/302/95, March 1998), should be taken into consideration. Changes in the impurity profile would not necessarily trigger non-clinical studies. However the MAH should justify their strategy in this respect.

Non-clinical studies should be comparative in nature and should be designed to detect differences in response between the pre- and post-change products and not just the response *per se*. The pre- and post-change products should be compared concurrently within the same study.

Sufficient information and cross-referencing to other sections should be provided in the non-clinical section to justify the approach taken in the design of the non-clinical comparability exercise. The following approach may be considered and should be tailored to the specific product concerned on a case-by-case basis. The approach taken will need to be justified in the non-clinical overview.

- *In vitro* studies:

Assays like receptor-binding studies or cell-based assays, many of which may already be available from quality-related bioassays, should normally be undertaken with the pre- and post-change products being tested concurrently using a comparative study design, in order to assess if any alterations in reactivity have occurred and to determine the likely causative factor(s) if comparability cannot be established.

- *In vivo* studies:

If there are specific uncertainties or concerns regarding pharmacokinetic parameters or pharmacodynamic effects relevant to the clinical application, and/or safety, *in vivo* studies in one or more relevant species and properly validated animal model may be considered. Greater reliance would be placed on results from studies in a species shown for the pre-change product to be a relevant model for man. The final formulation of the post-change product should preferably be used rather than the drug substance alone. Ideally, the formulation used in non-clinical comparability studies should be the same as that used in clinical trials to facilitate interpretation of data. State of the art methods should be employed.

In general and where the model allows, consideration should be given to monitoring a number of endpoints such as:

- Changes in pharmacodynamic parameters relevant to the clinical application, e.g. duration of action.

- Changes in pharmacokinetic parameters, e.g. clearance.
- Specifically designed toxicological observations (in-life and post-mortem). The study design should be justified, taking into consideration the intended duration of clinical use.
- The immune response, e.g. antibody titres, neutralising capacity, cross-reactivity. Although the predictive value of animal models for immunogenicity in humans is low, (comparative) immunogenicity endpoints should be included in repeated dose toxicity studies to aid in the interpretation of these studies.

Ongoing consideration should be given to the use of emerging technologies. For example, *in vitro* techniques such as e.g. ‘real-time’ binding assays may prove useful. *In vivo*, the developing genomic/proteomic microarray sciences may, in the future, present opportunities to detect minor changes in biological response to pharmacologically active substances.

### 4.3 Clinical studies

Requirement for a dedicated clinical comparative efficacy and safety study is dependent on the stage of development, the type of change being introduced and the impact on quality attributes. Companies frequently introduce changes during the development of a given product prior to marketing authorisation application. If a manufacturing change is introduced before the confirmatory trial(s), the additional data required for the comparability exercise might be fewer than those needed for changes introduced after the confirmatory trial(s) or after approval.

- *Changes in the manufacturing process before initiation of confirmatory trials*

For this situation, adequate data from physico-chemical and biological *in vivo and in vitro*, and sometimes also non-clinical or clinical comparability studies such as a single dose pharmacokinetic study, are generally sufficient in order to demonstrate that the non-clinical and clinical data obtained before the change has been introduced are still valid and can be extrapolated to the post-change product.

- *Changes in the manufacturing process during confirmatory trials*

Changes during the confirmatory study are discouraged; if these occurs it is recommended that the Applicant seeks scientific advice

- *Changes in the manufacturing process after confirmatory trials or after approval*

If a manufacturing change takes place after the confirmatory trial(s) has been performed, or after approval, a more thorough comparability exercise is generally required, including physicochemical and biological *in vitro* studies, and may include clinical pharmacokinetic and / or pharmacodynamic comparability studies. If this comparability exercise cannot rule out an impact on the efficacy and safety profile of the drug, additional clinical study (ies) may have to be performed. Deviations from this conceptual level should be justified.

- *Further criteria influencing the requirement of comparative clinical data*

Further important issues that should be taken into account when designing and justifying the clinical program include results of any non-clinical studies and any clinical experience gained with the pre-change product and other products in the same category, if relevant, with respect to:

- *The relationship between dose/exposure and efficacy/safety*
- Whether a dynamic marker has been accepted as a surrogate marker for clinical efficacy/safety
- The relationship between dose/exposure and this surrogate marker

- Drug/receptor(s) interaction
- Disease-specific mechanisms of action
- Target organ(s) for activity and toxicity
- Mode of administration

### ***Pharmacokinetic studies***

Pharmacokinetic studies are an essential part of the clinical comparability exercise. Since the aim is to demonstrate comparability and not the characterization of clinical pharmacology of the product *per se*, such studies should be comparative.

A single-dose crossover study is, in principle, acceptable due to usually lower variability than in head-to-head comparisons. However, factors like immunogenicity and its possible consequences related to alterations of pharmacokinetics and/or pharmacodynamics should be considered

The route of administration should be in accordance with the intended clinical use. If the product can be administered by more than one route (e.g. s.c. and i.v.), it may become necessary to test all routes. The selected dose should be in the steep part of the dose-response curve, in order to detect relevant differences. The choice of the population (healthy volunteers versus patients) is primarily driven by the mode of action of the product. Since PK and PD studies are preferably combined, the choice of the study population should be selected based on the PD effects to be shown, i.e. whether the PD effects are detectable in a relevant manner in the population of choice. The possibility of a carry-over effect should be considered when designing such crossover study.

The design of comparative PK studies should not necessarily mimic that of the standard “clinical comparability” design (CHMP/EWP/QWP/1401/98), since similarity in terms of absorption/bioavailability is not the only parameter of interest. Differences in elimination characteristics between products e.g. clearance and elimination half-life should be explored.

### ***Pharmacodynamic studies***

Pharmacodynamics should preferably be evaluated as part of the comparative pharmacokinetic study, since alterations in pharmacodynamics can sometimes be explained by altered kinetics. Again, studies should be comparative in nature and not merely show the pharmacodynamics of the product *per se*.

- *Markers for primary and secondary pharmacodynamics*

As a principle, an endpoint should be selected that fulfils the following requirements: (1) sensitive enough to detect small differences, (2) measurable with sufficient precision, (3) clinically relevant for the target population. Care should be taken in these cases to investigate a reasonable dose range to demonstrate assay sensitivity. Studies at more than one dose level may be useful (see ICH topic E10). The choice of marker(s) should be justified and the margin defining equivalence should be pre-specified and justified.

In this respect, the choice of the population should be justified. Demonstration of certain primary or secondary PD markers might only be apparent in the diseased population as opposed to healthy volunteers. For example, immunomodulators aiming at modulating pathologically altered immune effector cells would not necessarily exert similar effects in healthy volunteers.

- *PD markers as substitutes for efficacy*

Usually in clinical trials, efficacy is defined by one or more clinical endpoint(s). Sometimes PD markers are used. A pharmacodynamic marker is a relevant marker for efficacy, if therapy-induced changes in that marker to a large extent can explain changes in clinical outcome.

PD markers are usually more sensitive to changes in activity of the product and can be assessed earlier than clinical endpoints and, therefore, they might in some cases represent the most appropriate endpoint. However, as the goal of the comparative exercise is showing equivalence of the products, usually data are needed concerning the quantitative relationship between the PD marker and the clinical endpoint to enable defining and justifying the equivalence margin in terms of efficacy. Sometimes it may be useful to use more than one PD marker.

Research in surrogate endpoints by the applicants / marketing authorisation holders is encouraged, since a surrogate marker will be useful in the course of product development.

### ***Efficacy studies***

- *Study design*

If no suitable markers exist, or if pharmacodynamic studies fail to establish comparability clearly, a comparative equivalence clinical trial using clinical endpoints will be required. Again, studies should be comparative in nature, comparing the post-change product with the pre-change product. Equivalent therapeutic efficacy should be demonstrated. Usually, clinical studies should be randomised, double blind, to avoid bias. Possible differences in efficacy should normally be investigated in studies with the highest probability of showing a difference (see ICH topic E10).

The acceptable equivalence margin should be set taking into account the product release specifications, clinical relevance and statistical considerations, and be pre-specified. The sample size required should not solely be based on considerations on clinical efficacy, but also on detection of differences in safety (see below).

If an equivalence trial design is not feasible, other designs should be explored and their use discussed with the competent authorities.

- *Selection of the most relevant patient population/therapeutic indication*

Since therapeutic proteins can be used for different indications and/or different patient populations, differential impact on efficacy and/or safety needs to be considered. Usually, a patient population or indication should be chosen where differences are best distinguishable, i.e. the most sensitive model for efficacy. The choice, however, will also depend on the susceptibility and vulnerability of this population to potential safety problems, and will have to be justified by the applicant. The Applicant needs to thoroughly discuss and justify if efficacy and safety results of the comparative study in one indication or population can reasonably be assumed to be applicable to other populations or indications.

- *Selection of appropriate endpoints*

As a principle, endpoints should be selected that show differences with the highest accuracy. The clinical requirements for comparative studies being part of a comparability exercise can be different from those for conventional confirmatory studies. For marketed products, the endpoints might not necessarily be those, which had been selected for the confirmatory trials if they are not sufficiently suitable for detection of differences. As noted above, pharmacodynamic or other markers like imaging techniques can be more suitable than genuine clinical endpoints. The choice of endpoints needs to be fully justified.

- *Study duration*

The study duration is essentially driven by the choice of the clinical endpoint. The duration should be sufficient to detect also minor differences with sufficient accuracy. Available data from literature should be included in the justification and discussion of study duration. Since safety data evaluation is an essential part of the clinical comparability exercise, the study duration should also be determined with the aim of detecting relevant differences of safety findings adequately.

### ***Clinical safety and pharmacovigilance requirements***

Even if the efficacy is shown to be comparable, the post-change product may exhibit a difference in the safety profile (in terms of nature, seriousness, or incidence of adverse reactions). Pre-licensing safety data should be obtained in a number of patients sufficient to compare the adverse effect profiles of the pre- and post-change product. Care should be given to compare the type, severity and frequency of the adverse reactions between the pre- and post-change product.

Further studies post-licensing may occasionally be needed, e.g. pharmaco-epidemiological studies.

Applicants should in their discussion of adverse events not only include the incidence, but also possible differences in clinical presentation (duration, severity and seriousness, reversibility, response to treatment etc.).

The applicant should give a safety specification in the application dossier for the medicinal product under review. This includes a description of possible safety issues related to the changes in the manufacturing process.

- *Extent of the safety database*

In general, safety data can be gathered as part of the clinical study aiming at establishing equivalent efficacy. Study duration and sample size calculation should consider frequency, severity and seriousness of expected adverse events as well as the clinical setting of the use of the drug (intended for acute / chronic use etc.) (see also ICH guideline ICH E1). Again the general rule applies that the aim of such trial is not the detection of adverse events *per se*, but the evaluation of differences in occurrence.

- *Safety endpoints*

Specific safety endpoints should be selected, taking into account both the typical safety findings known for this product and/or this product class and potential other safety findings, which can be deduced from the mechanism of action. Since unexpected safety findings might occur, applicants are discouraged from setting up methods in the study protocols solely aiming at the detection of known safety issues. The evaluation of comparative immunogenicity should be integral part of safety evaluation (see Guideline on Immunogenicity of therapeutic proteins).

## **Risk Management Plan**

Within the authorisation procedure the applicant should present a risk management plan or after licensing of the product an update of the existing one in accordance with current EU legislation and pharmacovigilance guidelines. This should take into account risks identified during product development and potential risks.

Any specific safety monitoring imposed to the pre-change product and/or product class should be taken into consideration in the risk management plan, in accordance to EU legislation and guidelines on the Risk Management Plan (RMP). (*current policy to be followed - update the list of guidelines to include the mentioned here*).

In the PSURs submitted according current EU legislation, the marketing authorisation holder should address reports and any other information on tolerability that might be related to a process change. The cycle of submission of the periodic safety update reports (PSURs) might be amended (restarted) on a case-by-case basis.

### *Timing of the comparability data*

In principle, non-clinical and clinical data, if required, need to be available before implementation of the change in the manufacturing process, i.e. marketing the new version of the product. Depending on the product and the indication, approval of the process change might be based on pharmacodynamic data. Additional clinical/safety data, including immunogenicity data, may be provided after approval.
